## WORK IN PROGRESS

# A New Approach to The Ordering Principle Of the Stable Isotopes 

by Laurence Hecht
July 27-30, 2007

Three distinct systems describe the ordering of the key experimental singularities associated with the atom and nucleus: electron, proton, and neutron.
(1) The first in historical order describes a system of electron shells which close at $2,10,18,36,54$, and 86 electrons. The shells are composed of subunits of 2,6 , 10 , and 14 electrons, each capable of two states, known as positive and negative "spin." This system conforms to the spectral patterns of the elements, chemical combining properties, valences, and ionization potentials.
The ordering is consistent with the periods of the Mendeleyev table of the elements. However, it in no way sheds light upon Mendeleyev's almost forgotten starting hypothesis, that, contrary to the ideas of Galileo and Newton respecting mass, the ordering of the elements by atomic weights gives evidence of a periodicity.

> A new interpretation of the meaning of Planck's constant suggests a solution to the yet-unsolved question of the ordering of the stable isotopes.

The Moon Model of the nucleus, shown here in a drawing of two of the shells, employs a nesting of four of the five Platonic solids, similar to that conceived by Johannes Kepler to describe the Solar System. The 92 protons of all the naturally occurring elements fill the 46 vertices of two nested dodecahedra in the Moon Model.
(2) The study leading to the shell model of the nucleus, proposed by Maria Goeppert-Mayer in 1948, was undertaken at the prompting of Dr. Robert Moon and his friend the Nobel chemist James Franck, then collaborating at the Argonne National Laboratory. The hypothesis brings together a mass of evidence respecting the nuclear properties of the isotopes, to establish the existence of shells containing 2, 8, 20, 28, 50, 82, and 126 nucleons. The shells may consist of either neutrons or protons with no clear reason for the choice of one or the other.

The correspondence of the hypothesized shells with such widely varying properties as isotopic abundance, nuclear spin, neutron capture cross section, quadrupole moment and emission properties, are convincing evidence of its, at least partial,
validity. However, no reason is offered for the ordering principle. The hypothesis relies upon a variation of the conventionally accepted orbital model for the electron shells. In place of cause, statistical methods associated with attempts to resolve the $n$-body problem of nucleon attractions are substituted.
(3) Moon's nuclear model, formulated in 1986, was, intended in part, as a corrective to the shortcomings of GoeppertMayer's work. Moon's model describes proton shells corresponding to a nested sequence of Platonic solids, with singularities at $8,14,26,46,56,64,70,81,86$, and 92 protons.

The first three members of the series correspond to the elements that seem to be of greatest abundance in the Solar System. Moon's system describes the reason for the 14-member

Figures 1 and 2

## STABLE ISOTOPES BY MASS NUMBER

This proved to be the most convenient way initially to organize the data of the stable isotopes. It is a useful reference for any discussion of the topic. The charts consist of boxes numbered from 1 to 238, representing the mass number, and arranged for convenience in rows of 16. The stable isotopes are identified by chemical symbol, the most abundant denoted in bold; the other distinctions as noted in the legend.

An accompanying chart (Figure 2, link only) presents only the most abundant isotope of each element in the same format. Some of the basic features are seen at first glance: Two boxes, 5 and 8, are empty. Up to chlorine-35, no two isotopes share the same mass number. Following that, doublets and triplets occur. But, all triplets and many doublets contain radioactive species of very long half-life, (which are thus considered stable).

The tendency to ordering is indicated by coloration. For example, for mass numbers from 11 to 56 the most abundant isotopes of consecutive elements tend to form in couplets of odd-even. After 74-75, this changes to even-odd. When the couplets are separated by a pair of yellow boxes, the members of consecutive pairs are related by an alpha particle.
lanthanide series, and provides an explanation for the fission of the uranium nucleus. The filled shells 8 (oxygen), 26 (iron), 46 (palladium), 64 (gadolinium), and 92 (uranium) correspond to elements of high absolute or relative magnetic susceptibility.

The shells tend to fall near the minima of periodic properties such as atomic volume, melting point, and so forth. Certain classifiable properties of the stable isotopes are associated with each of the Moon nuclear shells.

The neutron capture cross-sections of the elements making up closed shells are low. The electric quadrupole moments of the closed shells are low and tend to rise to either side. The maximum number of neutrons in the stable isotopes in the first four shells are $10,16,32$, and 64 .

*     *         * 

None of the three orderings can completely describe the system of 280 stable isotopes. Why a particular element exhibits a
characteristic number of stable isotopes, falling within a defined mass range, and the reason for the abundance distribution of the isotopes, remain unexplained by any of the three hypotheses. In short, an ordering principle of the stable isotopes, equivalent in conceptual power to Mendeleyev's periodic system of the elements, is still wanting.

My efforts over the past year have caused me to examine a large amount of data related to the atomic and nuclear properties, in the hopes of finding a synthesis, with aid of the more

( $Z=$ protons; $N=$ neutrons; $A=$ mass number)
Table 1
PERIODIC TABLE OF THE STABLE ISOTOPES
This is an extension of the one prepared for my previous report ("Neutron Octaves in the Moon Nuclear Model," May 18, 2007). The distribution of neutrons by powers of 2, when the isotopes are arranged according to the shells of the Moon model, may be seen here. It provides the data for Figure 3.
powerful tool of the Moon nuclear model. (Some of these are summarized in the form of appended charts and graphs.) Although I seem to get close with various approaches, I have reached nothing that would unite the three, apparently mutually contradictory, systems summarized above.

## Moon vs. Bohr

A recent rethinking of the assumptions behind Moon's efforts has led me to suspect a methodological error in my approaches thus far. My analysis would lead to the conclusion that the conventional picture of atomic electrons, despite its apparent fit to the Mendeleyev table and the data of spectroscopy, is funda-
mentally flawed. This goes to the question of the relationship of electromagnetic propagation and matter, the emission of radiation by electrons and so forth.

Recall that in Moon's conception, what we have called the Moon model, the Keplerian shells of the nucleus derive from a principle of ordering of space (space quantization), which also governs the configuration of electrons associated with electromagnetic propagation. The ratio of the impedance of free space to the maximum quantum Hall resistance in the solid state $(25,812.8$ ohms) is twice the fine structure constant (taken as $1 / 137$ ). Moon interprets this as evidence of a configuration of 68
(Text continued on p. 50)

## Shell 2: (Cube, last vertex), Octahedron

| Characteristics: $\mathrm{N}=8$ to 16, (8) |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Odd elements: All have 1 isotope; mass number $=2 Z+1$. |  |  |  |  |  |  |
| Even elements: All have 3 isotopes; mass numbers = $2 Z, 2 Z+1,2 Z+2$. Most abundant is $2 Z$. |  |  |  |  |  |  |
| Z | N | Nuclide | \% Abundance | Nuclear Spin | Mag. Moment | Number of Isotopes |

## Shell 3: Icosahedron

Characteristics: $\mathrm{N}=16$ to 32 , (16)
Odd elements: Prime atomic number species have 2 isotopes; non-prime have 1.
Even elements: Mass number range is 5 , (except Ca ). After calcium, most abundant isotope is $2 Z+4$.

(Text continued from p. 39)
paired electrons, plus one unpaired, operative in the propagation of electromagnetic radiation. The 137 electrons fill the 69 axes $(3 \times 23)$ of three saturated palladium structures.
Moon's conception is susceptible of the following interpretation, which gives an intelligible representation for Planck's law. The Planck constant is a measure of action, that is, of a quantity of work over a period of time, or the work exerted by a given mass acting at a certain velocity over a given length. The value of the

Planck quantum is equivalent to the product of the mass of the electron, the velocity of light, and the Weber critical length into the inverse fine structure constant (137). $\quad h=137 m_{e} \cdot c \cdot \rho$, where $h$ is the action constant, $m_{e}$ the mass of the electron, $c$ the velocity of light in vacuo, $\rho$ the Weber critical length ( $=e^{2} / m_{e} \cdot c^{2}$ ).

The physical interpretation is that each of the Weber-paired electrons in the configuration of 137 described by Moon, completes one oscillation at a mean velocity $c$. The result is the minimal measurable action in the extranuclear domain. The Planck energy ( $E=$

Figure 3

## STABLE ISOTOPES BY NEUTRON NUMBER

The chart is an attempt to illustrate the neutron octaves and make evident other features of the ordering by neutrons, rather than mass number. The so-called magic numbers, actually unexplained anomalies in the ordering of neutrons, 20, 28, and 50, are quite evident as extended horizontal displays. The number of isotopes per element, and their mass range, both absolute, and in relation to the other elements is visually apparent.

One unexplained feature is a tendency for the isotopes, above oxygen and of even neutron number, to occur in groups of three; an odd-numbered element is surrounded by two evens, as in Ti-20, V-28, Cr-28 (the numbers here denoting the neutron number).

The Binding Energy per Nucleon graphs were inserted to see if there was a relationship of binding energy to the shells. Shells 2 and 3 begin at valleys in the curve, and end at peaks. Shell 4 might be thought of the same. But the relationship does not hold consistently.

The series is not extended beyond barium. Shells 1, 2, 4 and 5 are links only.
$h \nu$ ) thus becomes intelligible as the measure of the work done by a configuration of 137 free electrons in the Moon configuration, vibrating at any given frequency.
What must now be considered is the relationship of electromagnetic radiation to its source in the atom or nucleus. For example, since Niels Bohr, the emission of light or other radiation from an excited atom has been explained as a shift in electron orbitals. The orbits were constructed to fit the energy equivalents of the observed radiation. The ad hoc assumption was introduced that the orbits must occur in quantized units of angular momentum to suit the Planck law.

In Moon's hypothesis, the radiation is quite intimately connected with the work done by a configuration of 137 electrons. To comprehend the atom, where it appears that a lesser number of electrons are bound in connection with the nucleus, we would like to know the relationship of these to the 137. It appears that the singularities we know through atomic and nuclear chemistry are a modification of what we might suppose as a potential within space for the joining of the electron singularities into three dodecahedra. The excitation of an atom which produces radiation, therefore, must have something to do with the relationship of that spatial potential to its reconfigured form in the atom.

So we overcome the abohrent.

Figure 4 (Click for figures)
ELECTRIC QUADRUPOLE MOMENTS
The quadrupole moments of the elements at closed proton shells in the Moon model occur at low points in the graph. The elements are indicated in yellow. Barium is the completion of the first half of the twin dodecahedron. Ytterbium (Yb) is the completion of the inner cube and octahedron of the lanthanide series. Thallium (TI-205) marks the completion of the second icosahedron. (The closing of the dodecahedron occurs beyond the range of stable isotopes.)

Figure 5 (Click for figure) LOG OF MAGNETIC SUSCEPTIBILITY Oxygen, iron, palladium, gadolinium, and uranium show very high magnetic susceptibility. This chart is revived from studies reported in 2004, as it points to an anomaly expressed by the Moon model respecting a characteristic which is not normally considered nuclear.
